Chapter 1: Gross Domestic Product

Jesús Bueren

Católica-Lisbon

2026–2027

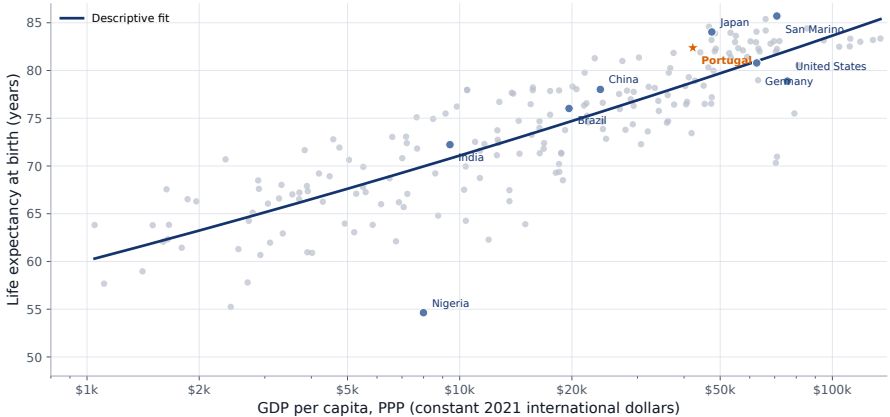

What would we really like to measure?

- Our ultimate interest is **welfare**: how well people are able to live.
- Welfare is multidimensional: health, consumption, education, security, relationships, leisure, freedom, and the environment all matter.
- There is no natural unit in which to add these dimensions, and people need not assign them the same weights.

So why begin with GDP?

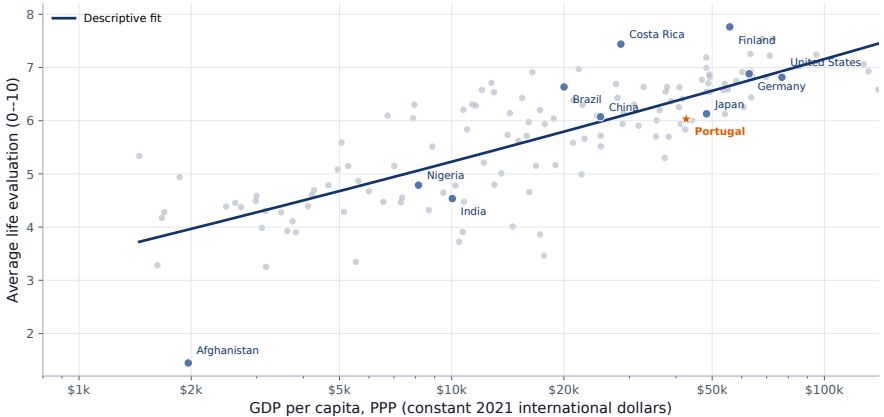

GDP per person is measurable, comparable across countries and time, and strongly associated with many outcomes that people value.

Do people in richer countries live longer?

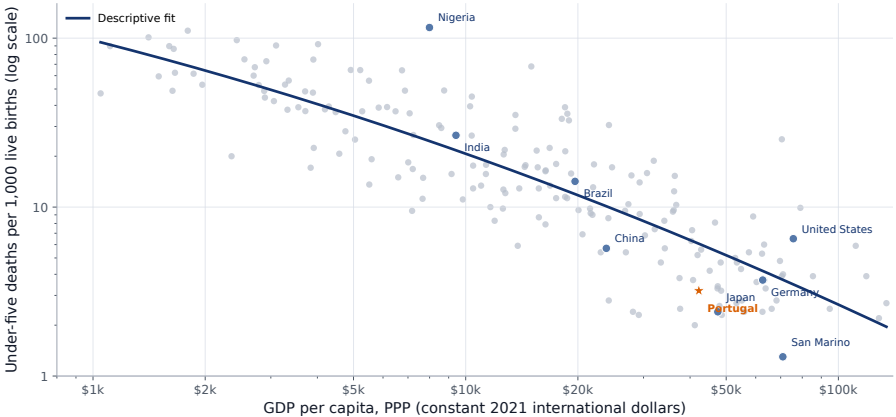

Source: World Bank World Development Indicators. Latest available observations; N = 199.

Are people in richer countries more satisfied with their lives?

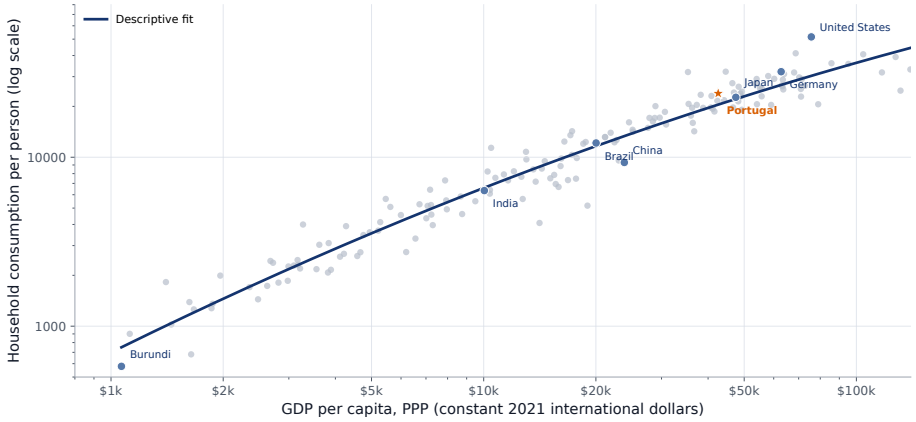

Source: World Happiness Report 2026 and World Bank. Latest available observations; N = 138.

Do more children survive in richer countries?

Source: World Bank World Development Indicators. Latest available observations; N = 188.

Can households consume more in richer countries?

Source: World Bank World Development Indicators. Latest available observations; N = 166.

GDP is a useful proxy, not welfare itself

- GDP per person is closely associated with material consumption, longer lives, child survival, and life satisfaction.
- The gains tend to become smaller at higher income levels.
- Countries with similar GDP can still deliver different outcomes.
- These are cross-country correlations, not proof that GDP alone causes better lives.

Our working position

GDP is an informative starting point for measuring economic performance—but never the complete scorecard for social welfare.

GDP Accounting: Our Roadmap

We now turn from motivation to measurement. We will ask:

1. **How is GDP computed?**
   We will build GDP using production, income, and expenditure—three different but equivalent approaches.

2. **What does GDP actually measure?**
   We will clarify what is included, what is excluded, and how GDP should be interpreted.

3. **How can we compare GDP across countries?**
   We will explain GDP at purchasing power parity (PPP) and why differences in national price levels matter.

US GDP in 2017

Table: US GDP in 2017 according to the three methods (billions of dollars). Source: BEA.

Production		Income		Expenditure	
Agriculture	169	Employee Compensation	10,421	Consumption	13,321
Mining	269	Corporate Profits	1,807	Investment	3,368
Utilities	308	Proprietors' Income	1,501	Gov. Spending	3,374
Construction	781	Rental Income	730	Exports	2,350
Manufacturing	2,180	Depreciation	3,116	Imports	-2,929
Wholesale & Retail	2,261	Interest Income	768		
Transportation	609	Taxes	1,286		
Media	1,051	Statistical Discrep.	-143		
Finance & Insurance	1,466				
Real Estate	2,591				
Professional Services	2,426				
Education & Health	1,700				
Arts & Entertainment	805				
Other Services	416				
Government	2,454				
Total	**19,485**	**Total**	**19,485**	**Total**	**19,485**

GDP Accounting

- GDP can be measured in three equivalent ways:
  - production
  - income
  - expenditure
- Using the expenditure approach, GDP is given by:

$$Y = C + I + G + X - M$$

- Y: Gross Domestic Product
- C: Private consumption
- I: Investment
- G: Government purchases
- X: Exports
- M: Imports

- Key idea: whenever goods and services are produced, their value appears as someone's expenditure and someone's income.
- In the next slides, we build intuition through a series of examples for why:

Production = Income = Expenditure.

GDP Accounting

- João, who is self-employed, produces beer and sells it to Ana Maria for $1.
- Ana Maria drinks it.

GDP from the three approaches (in dollars)

Production		Income		Expenditure	
Beer production	1	João's income	1	Ana Maria's consumption	1

- Production: measures the value of the beer that was produced, which is $1 (Manufacturing)
- Income: how much income is derived from productive activities: João obtains $1 of income from selling the beer. (Proprietor's income: income from self-employment)
- Expenditure: The expenditure approach looks at what the production was used for. (Consumption)

Value Added

- Production typically takes place in several stages.

  Someone's output becomes somebody else's input.

- We want to measure the **value added** at the end of the production process, avoiding **double counting**.

The Pastel de Nata Economy

- Alice owns a company that makes cream filling. She pays Bob \$0.50 to mix milk, eggs, and sugar.
- The company sells the filling to Carol, who runs a pastelaria, for \$0.80.
- Carol uses the filling to bake a pastel de nata, which she sells to Daniel for \$1.
- Daniel eats the pastel de nata (and contributes nothing further to GDP).

GDP from the three approaches (in dollars)

Production		**Income**		**Expenditure**	
Manufacturing (filling)	0.8	Wages (Bob)	0.5	Consumption (pastel de nata)	1.0
Services (pastelaria)	0.2	Profits (Alice)	0.3		
		Proprietor income (Carol)	0.2		
Total	**1.0**	**Total**	**1.0**	**Total**	**1.0**

Avoiding Double Counting

- It would be a **mistake** to add the value of the filling to the value of the pastel de nata, because the filling was **used up** in making the pastel de nata.
- The **value added** by the pastelaria is the difference between the final value of the pastel de nata ($1) and the value of the filling ($0.80):

$$\text{Value added (Carol)} = 1.00 - 0.80 = 0.20$$

- Calculating GDP this way ensures that the total value of output is **consistent across the three approaches**:

$$\textbf{Production} = \textbf{Income} = \textbf{Expenditure} = \textbf{\$1.00.}$$

Forms of Investment

- Investment takes different forms — but all involve producing something that will help produce more in the future.

(a) **Equipment:** Elon builds a robot barista and sells it to a coffee shop for $1,000. The cost of producing it is made up of worker's wages of $600. The robot will make cappuccinos for years to come.

Production		**Income**		**Expenditure**	
Manufacturing (robot)	1,000	Wages Profits	600 400	Investment (equipment)	1,000
Total	**1,000**	**Total**	**1,000**	**Total**	**1,000**

Forms of Investment (II)

- **(b) Inventories:** Caffeine Inc. produces 1,000 bags of coffee beans worth $30,000 but hasn't sold them yet. These beans are stored in the warehouse — an increase in inventories is also **investment**.

Why? Because the coffee beans will be sold or roasted later — they are goods that will help future production (coffee sales).

Production		**Income**		**Expenditure**	
Manufacturing (coffee beans)	30,000	Wages Profits	20,000 10,000	Investment (inventories)	30,000
Total	**30,000**	**Total**	**30,000**	**Total**	**30,000**

Inventories in the Next Period

Period $t+1$: Caffeine Inc. sells the previously produced coffee beans. There is **no new production**.

Production		**Income**		**Expenditure**	
No new production	0	*No new income*	0	Consumption	30,000
				Investment (inventories)	-30,000
Total	**0**	**Total**	**0**	**Total**	**0**

Durables (I)

- The line between consumption and investment isn't always clear.
- A house produces "housing services" for years — that's why residential construction counts as investment.
- Similarly, a refrigerator, a TV, a car, or even a fancy pair of sneakers produces services over time.
- How does GDP accounting treat these durable goods?

Fun with Durables

- **(a) TV:** Panasonic builds a TV (at zero cost!) and sells it to Bob for $500.

Production		**Income**		**Expenditure**	
Manufacturing (TV)	500	Corporate profits	500	Consumption (durables)	500
Total	**500**	**Total**	**500**	**Total**	**500**

- **(b) Watching the TV:** Bob watches the TV he bought last year. Nothing new is produced:

Production	0	Income	0	Expenditure	0

Durables (II)

- **(c) House:** A property developer builds a house (at zero cost) and sells it to Claire for $100,000.

Production		Income		Expenditure	
Construction (house)	100,000	Corporate profits	100,000	Investment (residential)	100,000
Total	**100,000**	**Total**	**100,000**	**Total**	**100,000**

- **(d) Living in the house:** Claire enjoys the house she bought last year. Imputed rent (what it would cost to rent) is $7,000/year:

Production		Income		Expenditure	
Housing services	7,000	Imputed owner income	7,000	Consumption	7,000

Conceptual point: TVs and houses are produced once but enjoyed for a long time.

- TVs $\rightarrow$ treated as "consumed at purchase".
- Houses $\rightarrow$ treated as "investment", with housing services measured each year.

Foreign Production and GDP

Imports

- GDP includes everything produced **within the country**.
- Goods produced abroad are **not included in GDP**, even if residents consume them.

Car Adventure

- Andy wants a supercar. The manufacturer buys parts from Japan for $10, uses half in production, and sells the car to Andy for $20. No other costs.

Production		**Income**		**Expenditure**	
Car Manufacturing	15	Corporate profits	15	Consumption	20
				Investment (inventory)	5
				Imports	-10
Total	**15**	**Total**	**15**	**Total**	**15**

Foreign Production and GDP

Exports

- GDP includes goods **produced domestically**.
- If they are sold to **foreign residents**, they count as **exports**.

Example: Pastéis Go International

- A bakery in Lisbon produces boxes of pastéis de nata worth $10.
- The boxes are shipped to a café in Berlin.
- The buyer is a **foreign resident**.

Production		**Income**		**Expenditure**	
Bakery production	10	Wages and profits	10	Exports	10
Total	**10**	**Total**	**10**	**Total**	**10**

Do Imports Really "Subtract" from GDP?

A common media/political claim:

"When net exports are negative, that is, when a country runs a trade deficit by importing more than it exports, this subtracts from growth" — Peter Navarro (former top White House trade advisor).

Economist's clarification:

- The GDP identity $Y = C + I + G + (X - M)$ includes $(X - M)$ for accounting, not causation.
- Imports are first included in $C, I,$ or G, then subtracted to exclude foreign production.
- As a result, imports do not reduce GDP — they ensure GDP counts only **domestic** production.

The Government in GDP

- The government is a major producer of goods and services.
- Many services are provided directly (education, defense, etc.), so there is **no market price**.
- To include them in GDP, they are valued at their **cost of production**.

Example: The Government as a Producer

1. Public Education

Production		Income		Expenditure	
Public Education	85,000	Wages	85,000	Government	85,000

2. Public Concert

Production		Income		Expenditure	
Public Concert	85,000	Wages	65,000	Government	85,000
		Rental income	20,000		
Total	**85,000**	**Total**	**85,000**	**Total**	**85,000**

Note: GDP is the same in both examples—even though one service is highly valued (education) and the other (concert) is not.

Taxes

VAT

- Joao sells lemonade for $10, including $1 VAT.
- He pays $6 to workers, keeps $3 as profit.
- Government collects $1 VAT.

Production		Income		Expenditure	
Lemonade sold	10	Wages	6	Private Consumption	10
		Profits	3		
		Taxes	1		
Total	**10**	**Total**	**10**	**Total**	**10**

Depreciation

Example: Coffee Beans Production

- A firm produces coffee worth \$100 this period.
- It pays \$60 in wages.
- Depreciation of the machines producing the coffee: \$20.

Production		Income		Expenditure	
Coffee beans output	100	Wages	60	Consumption	100
		Net profits	20		
		Depreciation	20		
Total	**100**	**Total**	**100**	**Total**	**100**

Interpretation: Production = 100 = wages + gross profits=consumption
Gross profits = net profits + depreciation = 20 + 20 = 40

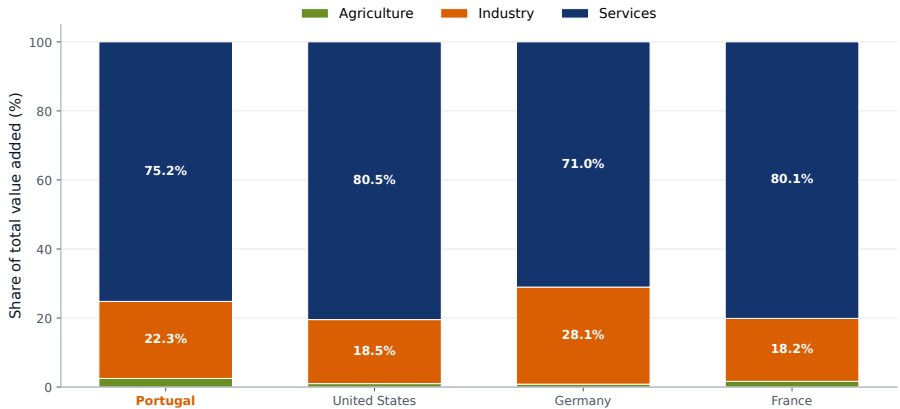

The Same GDP Total Offers Three Different Views

Approach	Question	What it reveals
Production	What is produced?	The economy's sectoral structure and how it changes with development
Income	Who receives the income?	The division of GDP between labor, capital, and taxes
Expenditure	Who buys the final output?	The roles of households, firms, government, and the rest of the world

One economy, three lenses

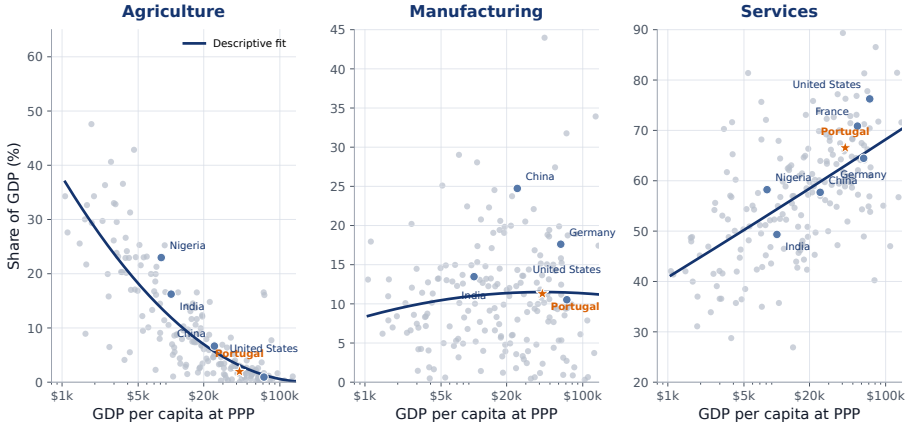

Each approach measures the same GDP, but highlights a different part of how the economy is organized.

Production Approach: What Do Economies Produce?

Source: World Bank World Development Indicators, 2021. Shares are normalized to total sector value added; industry includes construction.

Production Structure Changes with Income

Source: World Bank World Development Indicators. Latest observations: agriculture 2021–2025 (N=193); manufacturing 2020–2025 (N=189); services 2021–2025 (N=195).

As Economies Develop, Work Moves Across Sectors

Agriculture $\longrightarrow$ **Manufacturing** $\longrightarrow$ **Services**

Structural change:

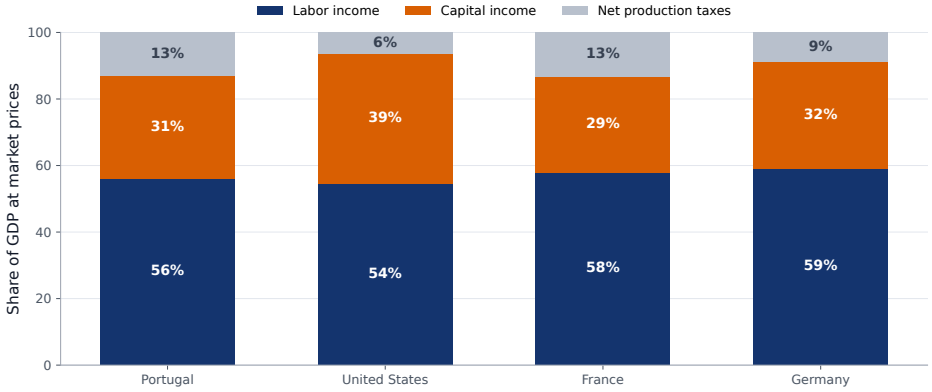

- Economic development changes what economies produce and where people work.

Why Do Workers Leave Agriculture?

1. Better machines and seeds raise output per farm worker.
2. More food can be produced with fewer workers, and food becomes cheaper.
3. But there is a limit to how much people want to eat. Food demand does not rise as fast as income.
4. Spending and workers move towards other goods: manufactured goods and services.

▸ Play the structural-change game

Income Approach: Who Receives GDP?

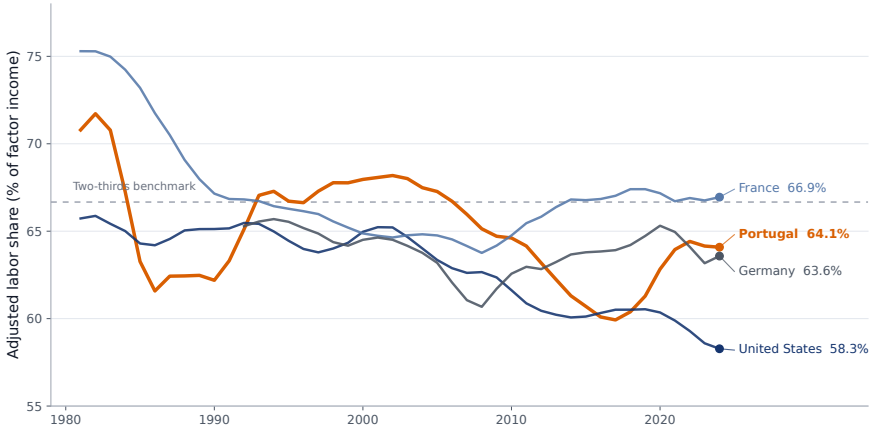

Source: European Commission AMECO, Spring 2026; 2024 data. Labor income is adjusted for self-employment; capital income is the residual after net production taxes.

Most GDP Is Paid to Labor

- Labor income is the largest component in every country: about 54–59% of GDP at market prices.
- Portugal, France, and Germany have similar splits between labor, capital, and taxes.
- The United States stands out for a larger capital share (39%) and lower net production taxes (6%).

Labor's Share Has Fallen Unevenly

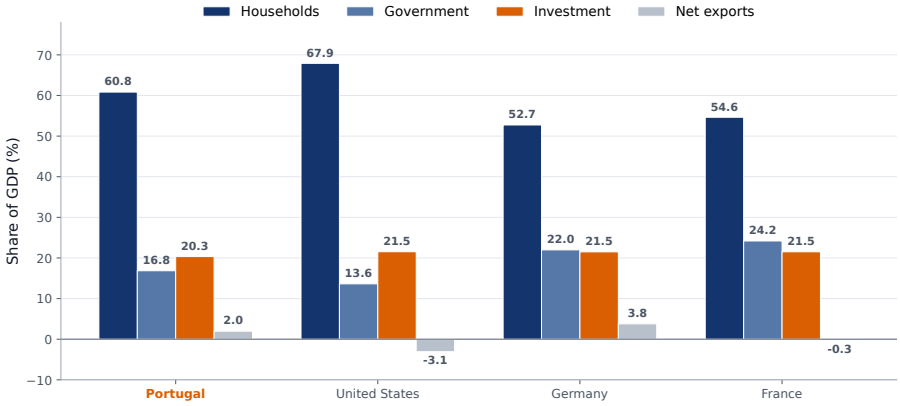

Source: European Commission AMECO, Spring 2026. Adjusted wage share, total economy, percentage of GDP at factor cost; three-year moving average; data through 2024.

Technology Is the Leading Explanation—but Not the Only One

- Recent surveys organize the explanations into five groups: technology, product markets, labor markets, capital markets, and globalization.
- The leading interpretation is **capital-augmenting technology and automation**: machines and software perform more tasks previously done by workers.
- Technology may also reshape product markets by favoring large, capital-intensive firms with lower labor shares.
- Markups, globalization, and workers' bargaining power remain possible competing or complementary channels.

Expenditure Approach: Who Buys the Final Output?

Source: World Bank World Development Indicators, 2024. Net exports equal exports minus imports; components may not sum exactly to 100 because of statistical discrepancies.

Consumption Dominates, but the Mix Differs

- **Household consumption is the largest component** in every country, ranging from about 53% of GDP in Germany to 68% in the United States.
- **Investment is remarkably similar**: around 20–22% of GDP in all four countries.
- **Government consumption is larger** in France and Germany than in Portugal and the United States.
- **Net exports can be positive or negative**: Germany and Portugal export more than they import, while the United States and France import more.

Is the Economy Producing More?

- GDP measures the value of production:

$$\text{GDP} = \text{prices} \times \text{quantities}.$$

- If GDP increases, this may be because:
  - more goods and services were produced;
  - prices increased;
  - or both.
- To determine whether the economy is actually producing more, we must **separate changes in quantities from changes in prices**.
- This is the distinction between **nominal GDP** and **real GDP**.

Making Comparisons across time

The Country of Snackistan

Snackistan produces only two things: burgers and yoga classes. Between 2023 and 2024, prices doubled, but production didn't change.

2017		2018	
Burger Manufacturing (50 balls, 10 dinar each)	500	Burger Manufacturing (50 balls, 20 dinar each)	1,000
Yoga Instruction (10 classes, 100 dinar each)	1,000	Yoga Instruction (10 classes, 200 dinar each)	2,000
Total	**1,500**	**Total**	**3,000**

nominal GDP (in dinars) doubled, but Snackistan didn't cook more burgers or stretch more yoga. **Prices doubled → Real GDP stayed the same.**

The Country of Expandia

Expandia produces only two goods: wheat and computers. Prices and quantities change differently between 2017 and 2018.

2017		2018	
Agriculture (10 tons of wheat, \$50 each)	500	Agriculture (11 tons of wheat, \$60 each)	660
Manufacturing (1 computer, \$1,000 each)	1,000	Manufacturing (2 computers, \$600 each)	1,200
Total	**1,500**	**Total**	**1,860**

GDP rose from \$1,500 to \$1,860 — but how much more stuff did Expandia actually produce?

Making Comparisons across time

When Prices and Quantities Both Change

In the previous example:

- Wheat output rose by **10%** (10 $\rightarrow$ 11 tons)
- Computer output doubled (**+100%**)
- Prices changed differently across goods

Question: How do we measure the growth of total production when both quantities and prices move in different directions?

$\Rightarrow$ Use a base year to keep prices fixed

Making Comparisons across time

Alternative 1: Measuring Real GDP with Base-Year Prices

We can measure 2018 production using 2017 prices.

2018, valued at 2017 prices	
Agriculture (11 tons of wheat, \$50 each)	550
Manufacturing (2 computers, \$1,000 each)	2,000
Total Real GDP (2018)	**2,550**

$$\text{Growth in real GDP} = \frac{2,550}{1,500} - 1 = 70\%$$

Expandia got richer in real terms — people have more stuff, not just higher prices.

Making Comparisons across time

Alternative 2: Measuring Real GDP with Final-Year Prices

We can also measure 2017 production using 2018 prices.

2017, valued at 2018 prices	
Agriculture (10 tons of wheat, \$60 each)	600
Manufacturing (1 computer, \$600 each)	600
Total Real GDP (2017)	**1,200**

$$\text{Growth in real GDP} = \frac{1,860}{1,200} - 1 = 55\%$$

Measured at 2018 prices, growth looks smaller because computer prices fell.

Making Comparisons across time

Real GDP with Chained Prices

- The base-year and current-year price methods can give very different results.
- The **chained method** combines both approaches.
- Idea:
  1. Start from a base year (say 2017).
  2. Compute growth between consecutive years twice:
     - once using initial-year prices,
     - once using final-year prices.
  3. Take an average the two growth rates.
  4. "Chain" this growth forward year by year.

$$2017 \xrightarrow{\text{avg } g_{2018}} 2018 \xrightarrow{\text{avg } g_{2019}} 2019$$

Making Comparisons across time

Real GDP with Chained Prices (Formulas)

$$g_t^I = \frac{\sum_i p_{i,t-1} q_{i,t}}{\sum_i p_{i,t-1} q_{i,t-1}} - 1 \qquad \text{(growth at initial-year prices)}$$

$$g_t^F = \frac{\sum_i p_{i,t} q_{i,t}}{\sum_i p_{i,t} q_{i,t-1}} - 1 \qquad \text{(growth at final-year prices)}$$

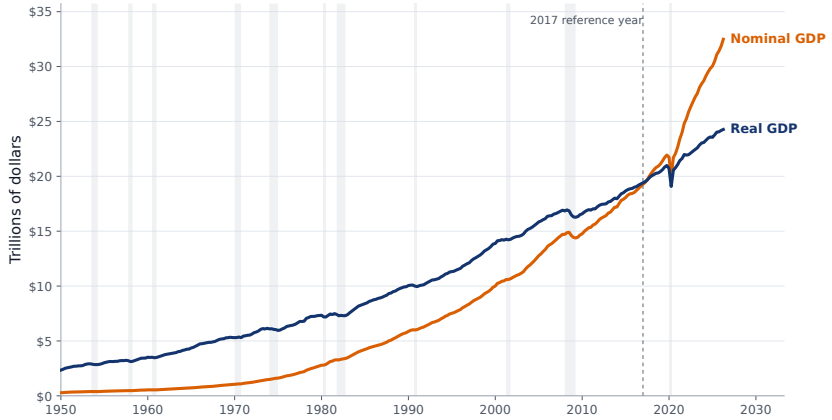

$$g_t = \sqrt{(1 + g_t^I)(1 + g_t^F)} - 1 \qquad \text{(geometric average growth)}$$

$$Y_t = Y_{t-1}(1 + g_t) \qquad \text{(chain forward real GDP)}$$

Intuition

The geometric average ensures a balanced measure between initial and final price weighting. Chaining allows comparison across many years without fixing prices from a distant base year.

Nominal and Real GDP in the United States

Source: BEA via FRED. Quarterly SAAR through 2026Q2. Real GDP: chained 2017 dollars. Shading: NBER recessions.

Comparing GDP Across Countries

- Suppose we want to compare GDP per capita in Portugal and Angola in 2024:

Country	GDP	Population	GDP per capita
Portugal	EUR 289.8 billion	10.7 million	EUR 27,100 per person
Angola	Kz 104.0 trillion	37.9 million	Kz 2.75 million per person

- Can we conclude that Angola produces more per person because 2.75 million is larger than 27,100?
- No. Euros and kwanzas are different units, so the numbers are not directly comparable.

Using Market Exchange Rates

- One option is to convert both values into U.S. dollars using market exchange rates:

$$\text{GDP per capita in US\$} = \frac{\text{GDP per capita in local currency}}{\text{local currency units per US\$}}$$

- In 2024, the World Bank reports:
  - Portugal: about \$29,300 per person.
  - Angola: about \$2,720 per person.
- Portugal therefore produces about 10.8 times more per person when GDP is converted at market exchange rates.

Using Purchasing Power Parity (PPP)

- PPP uses a conversion factor based on the prices of comparable goods and services:

$$\text{GDP per capita at PPP} = \frac{\text{GDP per capita in local currency}}{\text{PPP conversion factor}}$$

- In 2024:
  - Portugal: about 52,500 international dollars per person.
  - Angola: about 10,000 international dollars per person.
- At PPP, Portugal produces about 5.3 times more per person.

Why PPP Changes the Comparison

- Domestic services and non-traded goods are cheaper in Angola than in Portugal.
- Market exchange rates give these lower-priced goods and services a small value when Angola's GDP is converted into dollars.
- PPP uses price surveys to value comparable output at a common price level.
- The adjustment is larger for Angola:
  - Angola: PPP GDP per capita is about 3.7 times its market-rate value.
  - Portugal: PPP GDP per capita is about 1.8 times its market-rate value.

Example: Market Exchange Rates and PPP

Assume:

$$1 \text{ EUR} = 1{,}000 \text{ Kz}.$$

	Angola		Portugal	
Good	Quantity	Price	Quantity	Price
Haircuts	60	5,000 Kz	100	20 EUR
Wine bottles	6	120,000 Kz	10	120 EUR

Angola's GDP at the market exchange rate:

$$60(5{,}000) + 6(120{,}000) = 1{,}020{,}000 \text{ Kz} = 1{,}020 \text{ EUR}.$$

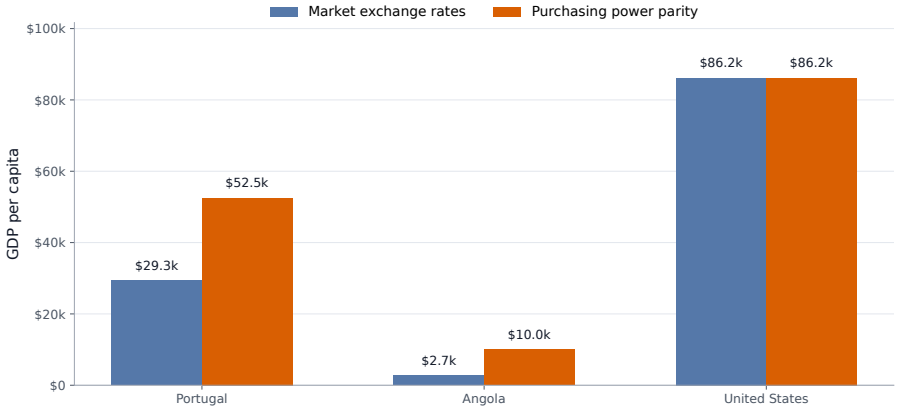

Angola's GDP valued at Portugal's prices:

$$60(20) + 6(120) = 1{,}920 \text{ EUR}.$$

Portugal's GDP at its own prices:

$$100(20) + 10(120) = 3{,}200 \text{ EUR}.$$

Market Rates and PPP: Portugal and Angola

Beyond GDP — Measuring Development

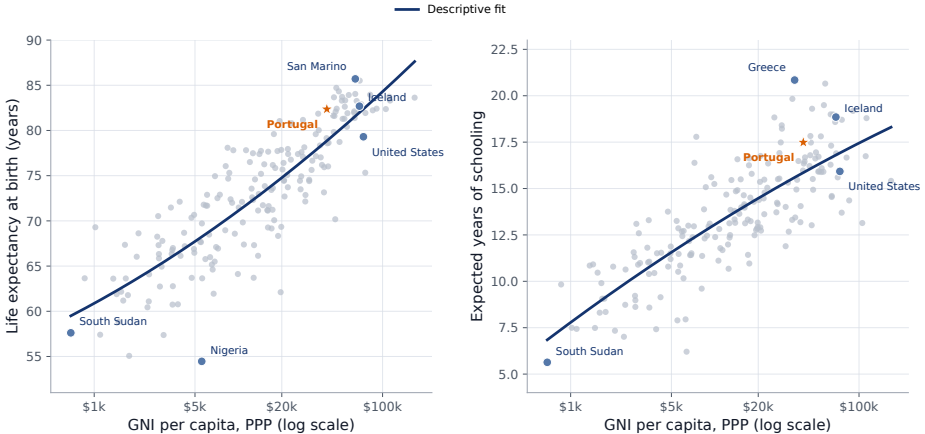

- As we saw in the in the first set of slides, GDP is a powerful indicator of economic activity, but it does not capture everything we care about.
- Economic **development** involves more than production and income:
  - Health and life expectancy
  - Education and literacy
  - Access to opportunities and basic services
  - Inequality and social inclusion
- In this last section, we discuss two alternative ways to measure well-being and living standards that explain why microfounded models are useful.
- We will first discuss a non microfounded approach, the Human Development Index (HDI), and then a more recent approach by Jones & Klenow (2016).

The Human Development Index (HDI)

- Created by the United Nations Development Programme (UNDP).
- Combines three key dimensions of human well-being:
  1. **Health:** measured by life expectancy at birth.
  2. **Education:** measured by average and expected years of schooling.
  3. **Income:** measured by GNI per capita (PPP adjusted).
- Each dimension is normalized between 0 and 1, and the HDI is their geometric mean:

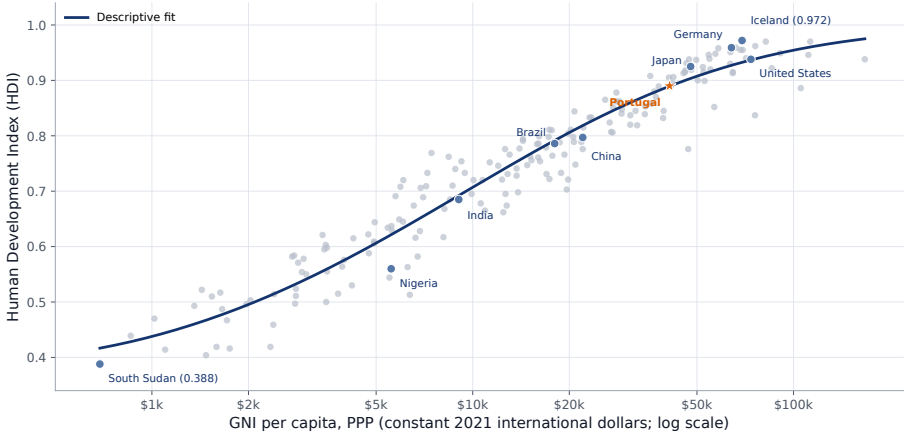

$$\text{HDI} = (I_{\text{health}} \cdot I_{\text{education}} \cdot I_{\text{income}})^{1/3}$$

The Human Development Index (HDI)

Source: UNDP Human Development Report 2025. 2023 observations; N = 193 countries. Income is in constant 2021 international dollars.

The Human Development Index (HDI)

Source: UNDP Human Development Report 2025. 2023 observations; N = 193 countries. Income is in constant 2021 international dollars.

The Human Development Index (HDI)

- One unsatisfying aspect of the HDI is that the scaling and weighting of the various factors is arbitrary.
  - What exactly is the HDI measuring?
  - Why convert variables into indices?
  - Why equal weights on the three factors?
- The weights could even be chosen to make a particular country look good, to receive more tourism or foreign aid.

Beyond GDP: Jones & Klenow (2016)

- Jones & Klenow propose instead a **welfare measure** similar in spirit to the HDI but grounded in **utility theory**.
- They aim to include aspects of life that GDP misses, focusing on:
  - **Consumption** – what people actually enjoy, not just produce,
  - **Inequality** – differences in consumption across people,
  - **Leisure and nonmarket production** – time spent outside work counts too,
  - **Life expectancy** – how long people live.
- We are going to explore the first two aspects: consumption and inequality.

Consumption and Utility

- Consumption matters because goods and services contribute to people's well-being.
- A **utility function**, $u(c)$, represents how consumption c contributes to well-being.
- We will use two simple assumptions:
  - **More is better:** higher consumption increases utility.
  - **Diminishing marginal utility:** an extra unit of consumption adds less to utility when consumption is already high.
- A simple example is:

$$u(c) = \log c.$$

- Consuming one more unit of consumption matters more to someone who initially consumes very little.

Utility and Inequality

- Consider two societies, each with two otherwise identical people:

	Person A	Person B	Average consumption
Equal consumption	10	10	10
Unequal consumption	5	15	10

- Average consumption is the same. But what if we evaluate welfare using **average utility**?
- With $u(c) = \log c$, the equal society has higher average utility:

$$\log 10 > \frac{1}{2} \log 5 + \frac{1}{2} \log 15.$$

- Transferring a unit of consumption from the richer person to the poorer person raises utility more for the poorer person than it lowers it for the richer person.
- Average consumption alone can therefore misses the welfare cost of inequality.

How Much Does Inequality Matter?

- The welfare cost of inequality depends on how quickly marginal utility falls as consumption rises.
- A common family of utility functions lets us vary this curvature:

$$u(c) = \begin{cases} \dfrac{c^{1-\sigma} - 1}{1 - \sigma}, & \sigma \neq 1, \\ \log c, & \sigma = 1. \end{cases}$$

- The parameter $\sigma \geq 0$ controls how much curvature we assume:
  - $\sigma = 0$: linear utility, so only average consumption matters.
  - $\sigma = 1$: log utility, as in our previous example.
  - Higher σ: a larger welfare cost of inequality, holding average consumption fixed.
- When consumption is uncertain, σ also measures **relative risk aversion**.

The Experiment: Comparing Portugal to the U.S.

- Imagine a person — let's call him **Pat the Alien** — who must choose where to live for a year:
  1. As a random resident in **Portugal**,
  2. As a random resident in the **United States**
- When choosing, Pat the Alien does not know which individual they will be:
  - a banker in Chiado or a waiter in Alfama,
  - a surfer in Ericeira or a stressed consultant in Lisbon,
  - alive or dead.
- In other words, Pat chooses under **uncertainty**.
- We need a way to quantify which country would be preferred: expected utility.

Expected Utility Across Individuals

- Pat the Alien knows the possible outcomes in each country (consumption, leisure, life expectancy) but not which one he will experience.
- Examples:
  - Ana or João in Portugal,
  - Mike or Diane in the U.S.
- Pat will prefer the country that gives the **highest expected utility**:

$$U = \mathbb{E}\left[\frac{c^{1-\sigma}}{1-\sigma}\right] = \frac{1}{N}\sum_{i=1}^{N}\frac{c_i^{1-\sigma}}{1-\sigma}$$

- This is a simple application of **expected utility theory**: uncertain outcomes are evaluated by weighting each possible utility by its probability.

The Role of Risk Aversion (σ) in Utility

- In expected utility theory, people's attitudes toward risk are captured by the **concavity of the utility function**.
- We use concavity in models to capture the idea that **most people dislike uncertainty** and therefore Pat the alien would prefer countries with lower inequality.
- Mathematically, holding leisure (ℓ) and life status (a) constant, utility is a function of consumption c:

$$u(c) = \frac{c^{1-\sigma}}{1-\sigma}$$

Pat the Alien and Risky Choices

- Suppose there are two people in Portugal: one rich (c_{rich}) and one poor (c_{poor}).
- Pat the Alien could end up in either situation with probability $1/2$.
- Pat is **risk averse** if he prefers a the average consumption over facing uncertainty:

$$u\left(\frac{c_{\text{rich}} + c_{\text{poor}}}{2}\right) > \frac{u(c_{\text{rich}}) + u(c_{\text{poor}})}{2}$$

Concavity and Marginal Utility

- The concavity of the utility function is controlled by σ:
  - High $\sigma \rightarrow$ very concave: Pat strongly dislikes inequality and risk.
  - Low $\sigma \rightarrow$ almost linear: Pat is less sensitive to differences across states.

How Do We Choose σ in Practice?

- People have different attitudes towards risk $\rightarrow$ we pick σ to represent an average individual: Pat.
- Empirical methods:
  - Investment choices: how much risk vs. average return are people willing to bear?
  - Insurance decisions: willingness to pay for smoothing consumption across uncertain states.
- Estimates range from $\sigma \approx 1$ (mildly risk averse) to $\sigma \approx 10$ (very risk averse).
- When choosing where Pat want to live, σ determines how much Pat cares about inequality:
  - High $\sigma \rightarrow$ unequal country looks risky: egalitarian countries become more attractive to Pat
  - Low $\sigma \rightarrow$ countries with higher expected income are more attractive

The Value of Life Expectancy ($\bar{u}$)

- Pat the Alien does not know is he will be dead or alive.
- Suppose Pat's age is randomly drawn from 0 to 100:
  - If his age exceeds life expectancy in the country, he is dead $\rightarrow$ utility $= 0$
  - If he is alive $\rightarrow$ utility $= \bar{u} + \frac{c^{1-\sigma}}{1-\sigma} - \theta(1-\ell)^2$
- Everyone alive gets the baseline utility $\bar{u}$ in addition to consumption and leisure utility.

The Value of Leisure and Non-Market Production (θ)

- People can spend their time in different ways:
  - Market work $\rightarrow$ counted in GDP
  - Non-market activities $\rightarrow$ not counted in GDP (cleaning, cooking, childcare)
  - Pure leisure $\rightarrow$ reading, watching TV, surfing, etc.
- In our utility function, ℓ is the fraction of time spent on non-market and leisure activities.
- The parameter θ captures how much people value non-market activities (or dislike market work).
- How can we measure θ?
  - Look at trade-offs people make between consumption and free time
  - Use choices like labor force participation, retirement age, weekly work hours, holidays
  - Higher $\theta \rightarrow$ people work less, enjoy more leisure and non-market activities
- By matching observed time allocation between market and non-market activities, we can estimate θ.

Comparing Living Standards Across Countries: Intuition

- We want a metric that tells us **how much better or worse life is in Portugal vs. the U.S.** in an intuitive way.
- Expected utility is great for theory, but *utiles are abstract*. Students, policymakers, and citizens care about consumption, leisure, and life expectancy in **familiar units**.
- Enter λ^{PT}: a **consumption scaling factor** for the U.S. that makes a random resident just as happy as in Portugal:

$$\frac{1}{N}\sum_{i=1}^{n} u(\lambda^{PT} c_i^{US}, \ell_i^{US}, a_i^{US}) = U^{PT}$$

- Intuition:
  - $\lambda^{PT} > 1$: You need more U.S. consumption to match Portugal $\rightarrow$ Portugal is "better" in welfare terms.
  - $\lambda^{PT} < 1$: Portuguese residents need more consumption to match the U.S. $\rightarrow$ U.S. is "better".

Comparing Living Standards Across Countries: Computation

- Step 1: Compute the expected utility in Portugal:

$$U^{PT} = \frac{1}{N}\sum_{i=1}^{N} u(c_i^{PT}, \ell_i^{PT}, a_i^{PT})$$

- Step 2: Solve for λ^{PT} in:

$$U^{PT} = \frac{1}{N}\sum_{i=1}^{N} u(\lambda^{PT} c_i^{US}, \ell_i^{US}, a_i^{US})$$

- Step 3: Interpret λ:
  - $\lambda^{PT} = 1.2 \rightarrow$ Portugal provides the same welfare as the U.S. with 20% higher consumption.
  - $\lambda^{PT} = 0.9 \rightarrow$ Portugal provides the same welfare as the U.S. with 10% lower consumption.

- Example: Suppose the expected utility in Portugal is 10.5 utiles and in the U.S. it is 11 utiles. Solving for λ^{PT} gives $\lambda = 0.95 \rightarrow$ Portugal is slightly worse off in equivalent U.S. consumption terms.

Results: Welfare (λ) vs. GDP per Capita

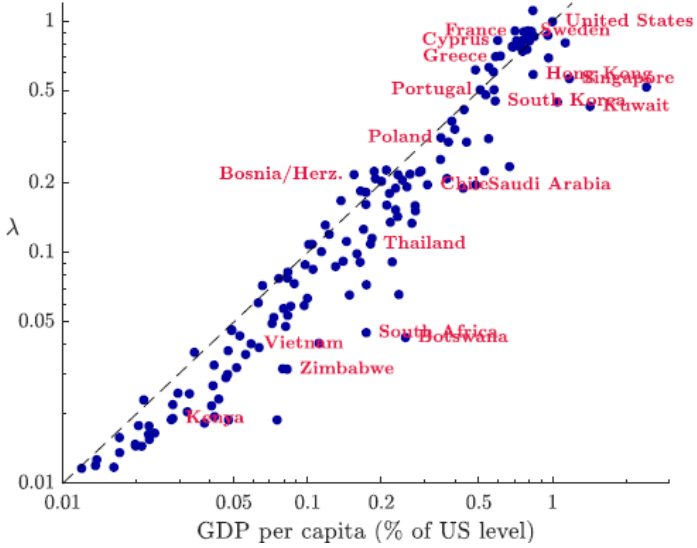

Figure 1: Relative GDP and welfare. Source: Jones and Klenow (2016).

HDI vs. Jones & Klenow (2016)

- **HDI:**
  - Simple composite index of life expectancy, education, and income
  - Assumptions are mostly implicit or not clearly listed
  - No clear rationale for how components are weighted
  - Provides a single number, but it is hard to know what it really means or how it was constructed
- **Jones & Klenow (2016):**
  - Grounded in utility theory—parameters explicitly defined
  - Incorporates consumption, leisure, life expectancy, and inequality
  - Assumptions are explicit: if you disagree, you can modify the model
  - Provides a number (λ) that is interpretable and based on the model structure

Takeaways for Economic Research

- Models are simplifications of reality, just like a map is a simplification of geography
- Explicit assumptions make progress possible:
  - We know what drives results
  - We can test alternative assumptions
  - We can propose improvements and extensions
- If you see a missing feature in current research:
  - Try writing a model that incorporates it
  - Analyze whether it makes a difference
  - This is the essence of research in economics: theory + data + clear assumptions

Game: Ten Workers, Three Sectors - Round 1

Your task

Your economy has **10 workers**. Allocate every worker to agriculture, manufacturing, or services to maximize household utility.

Production in Round 1

One worker in	Produces
Agriculture	1 unit of food
Manufacturing	1 manufactured good
Services	1 service

Output = workers × output per worker.

Household preferences

Consumption	Utility points
Food units 1–6	3 each
Additional food	0
Manufactured goods 1–6	2 each
Additional goods	0
Every service	1 each

Submit one answer for your team

Report the number of workers in each sector, the resulting quantities of food, goods, and services, and your **total utility points**. Surplus food or goods earns no points.

Game: Ten Workers, Three Sectors - Round 2

Agricultural productivity has doubled

Your economy still has **10 workers**. Reallocate every worker to maximize household utility under the new production technology.

Production in Round 2

One worker in	Produces
Agriculture	**2 units of food**
Manufacturing	1 manufactured good
Services	1 service

Output = workers $\times$ output per worker.

Household preferences

Consumption	Utility points
Food units 1–6	3 each
Additional food	0
Manufactured goods 1–6	2 each
Additional goods	0
Every service	1 each

Submit one answer for your team

Report the number of workers in each sector, the resulting quantities of food, goods, and services, and your **total utility points**. Surplus food or goods earns no points.

Game: Ten Workers, Three Sectors - Round 3

Productivity rises again

Your economy still has **10 workers**. Reallocate every worker to maximize household utility under the new production technology.

Production in Round 3

One worker in	Produces
Agriculture	**3 units of food**
Manufacturing	**2 manufactured goods**
Services	1 service

Output = workers × output per worker.

Household preferences

Consumption	Utility points
Food units 1–6	3 each
Additional food	0
Manufactured goods 1–6	2 each
Additional goods	0
Every service	1 each

Submit one answer for your team

Report the number of workers in each sector, the resulting quantities of food, goods, and services, and your **total utility points**. Surplus food or goods earns no points.
